(54) Title: PACKAGED STRAIN ACTUATOR

(57) Abstract

A modulator actuator assembly includes one or more plates or elements of electro-active material (71, 73) bonded to an electroded sheet to form a card. The card is sealed, and may itself constitute a practical device, such as a vane, shaker, stirrer, lever, pusher or sonicator for direct contact with a solid or immersion in a fluid, or may be bonded by a stiff adhesive to make a surface-to-object mechanical coupling of the plates through the sheet to a solid workpiece, device, substrate, machine, sample or other article. The laminated assembly supports the plates and provides a bending stiffness such that the tin plates do not deform to a breaking point, and a mechanical stiffness such that shear forces are efficiently coupled from the plates to the workpiece. In further embodiments, the card may include active circuit elements (75, 77, 78, 79) for switching, powering or processing signals, and/or passive circuit elements for filtering, matching or damping signals, so few or no connections to outside power or circuitry are required.

PACKAGED STRAIN ACTUATOR

Background of the Invention

5 The present invention relates to actuator elements such as may be used for active vibration reduction, structural control, dynamic testing, precision positioning, motion control, stirring, shaking, and passive or active damping. More particularly, the present invention relates to a packaged actuator assembly that is electronically controllable and may be used separately or adapted to actively suppress vibration, actuate structures, or damp
10 mechanical states of a device to which it is attached. As described in a subsequent section below, the assembly may be bonded or attached to a structure or system, thereby integrating it with the system to be actuated, controlled or damped.

 Smart materials, such as piezoelectric, electrostrictive or magnetostrictive
15 materials, may be used for high band width tasks such as actuation or damping of structural or acoustic noise, and also for precision positioning applications. Such applications frequently require that the smart material be bonded or attached to the structure that it is to control. However, general purpose actuators of these materials are not generally available, and typically a person wishing to implement such a control task must take raw, possibly non-
20 electroded, smart material stock, together with any necessary electrodes, adhesives and insulating structures and proceed to fasten it onto, or incorporate it into, the article of interest.

 For such applications, it becomes necessary to connect and attach these materials in such a way that the mechanical and electrical connections to the smart material
25 are robust and capable of creating strain within the smart member or displacing or forcing the system, and to couple this strain, motion or force to the object which is to be controlled. Often, it is required that the smart material be used in a non-benign environment, greatly increasing the chances of its mechanical or electrical failure.

30 By way of example, one such application, that of vibration suppression and actuation for a structure, requires attachment of a piezoelectric element (or multiple elements) to the structure. These elements are then actuated, the piezoelectric effect transforming electrical energy applied to the elements into mechanical energy that is distributed throughout the elements. By selectively creating mechanical impulses or changing strain within the
35 piezoelectric material, specific shape control of the underlying structure is achievable. Rapid actuation can be used to suppress a natural vibration or to apply a controlled vibration or displacement. Examples of this application of piezoelectric and other intelligent materials have become increasingly common in recent years.

In a typical vibration suppression and actuation application, a piezoelectric element is bonded to a structure in a complex sequence of steps. The surface of the structure is first machined so that one or more channels are created to carry electrical leads needed to connect to the piezoelectric element. Alternatively, instead of machining channels, two
5 different epoxies may be used to make both the mechanical and the electrical contacts. In this alternative approach, a conductive epoxy is spotted, i.e., applied locally to form conductors, and a structural epoxy is applied to the rest of the structure, bonding the piezoelectric element to the structure. Everything is then covered with a protective coating.

10 This assembly procedure is labor intensive, and often involves much rework due to problems in working with the epoxy. Mechanical uniformity between different piezoelectric elements is difficult to obtain due to the variability of the process, especially with regard to alignment and bonding of the piezoelectric elements. Electrical and mechanical connections formed in this way are often unreliable. It is common for the
15 conductive epoxy to flow in an undesirable way, causing a short across the ends of the piezoelectric element. Furthermore, piezoelectric elements are very fragile and when unsupported may be broken during bonding or handling.

Another drawback of the conventional fabrication process is that after the
20 piezoelectric element is bonded to the structure, if fracture occurs, that part of the piezoelectric element which is not in contact with the conductor is disabled. Full actuation of the element is thereby degraded. Shielding also can be a problem since other circuit components as well as personnel must generally be shielded from the electrodes of these devices, which may carry a high voltage.

25 One approach to incorporating piezoelectric elements, such as a thin piezoelectric plate, a cylinder or a stack of discs or annuli, into a controllable structure has been described in U. S. Patent No. 4,849,668 of Javier de Luis and Edward F. Crawley. This technique involves meticulous hand-assembly of various elements into an integral structure in
30 which the piezoceramic elements are insulated and contained within the structure of a laminated composite body which serves as a strong support. The support reduces problems of electrode cracking, and, at least as set forth in that patent, may be implemented in a way calculated to optimize structural strength with mechanical actuation efficiency. Furthermore, for cylinders or stacked annuli the natural internal passage of these off-the-shelf piezo forms
35 simplifies, to some extent, the otherwise difficult task of installing wiring. Nonetheless, design is not simple, and fabrication remains time-consuming and subject to numerous failure modes during assembly and operation.

The field of dynamic testing requires versatile actuators to shake or perturb structures so that their response can be measured or controlled. Here, however, the accepted methodology for shaking test devices involves using an electro-mechanical motor to create a linear disturbance. The motor is generally applied via a stinger design, in order to decouple the motor from the desired signal. Such external motors still have the drawback that dynamic coupling is often encountered when using the motor to excite the structure. Furthermore, with this type of actuator, inertia is added to the structure, resulting in undesirable dynamics. The structure can become grounded when the exciter is not an integral part of the structure. These factors can greatly complicate device behavior, as well as the modeling or mathematical analysis of the states of interest. The use of piezoelectric actuators could overcome many of these drawbacks, but, as noted above, would introduce its own problems of complex construction, variation in actuation characteristics, and durability. Similar problems arise when a piezoelectric or electrostrictive element is used for sensing.

Thus, improvements are desirable in the manner in which an element is bonded to the structure to be controlled or actuated, such that the element may have high band width actuation capabilities and be easily set up, yet be mechanically and electrically robust, and not significantly alter the mechanical properties of the structure as a whole. It is also desirable to achieve high strain transfer from the piezoelectric element to the structure of interest.

Summary of the Invention

An actuator assembly according to the present invention includes one or more strain elements, such as a piezoelectric or electrostrictive plate or shell, a housing forming a protective body about the element, and electrical contacts mounted in the housing and connecting to the strain element, these parts together forming a flexible card. At least one side of the assembly includes a thin sheet which is attached to a major face of the strain element, and by bonding the outside of the sheet to an object a shear-free and preferably stiff coupling is obtained between the object and the strain element in the housing.

In a preferred embodiment, the strain elements are piezoceramic plates, which are quite thin, preferably between slightly under an eighth of a millimeter to several millimeters thick, and which have a relatively large surface area, with one or both of their width and length dimensions being tens or hundreds of times greater than the thickness dimension. A metallized film makes electrode contact, while a structural epoxy and insulating material hermetically seal the device against delamination, cracking and environmental exposure. In a preferred embodiment, the metallized film and insulating

material are both provided in a flexible circuit of tough polymer material, which thus provides robust mechanical and electrical coupling to the enclosed elements.

By way of illustration, an example below describes a construction utilizing
5 rectangular PZT plates a quarter millimeter thick, with length and width dimensions each of one to three centimeters, each element thus having an active strain-generating face one to ten square centimeters in area. The PZT plates are mounted on or between sheets of a stiff strong polymer, e.g., one half, one or two mil polyimide, which is copper clad on one or both sides and has a suitable conductive electrode pattern formed in the copper layer for contacting the
10 PZT plates. Various spacers surround the plates, and the entire structure is bonded together with a structural polymer into a waterproof, insulated closed package, having a thickness about the same as the plate thickness, e.g., .30 to .50 millimeters. So enclosed, the package may bend, extend and flex, and undergo sharp impacts, without fracturing the fragile PZT elements which are contained within. Further, because the conductor pattern is firmly
15 attached to the polyimide sheet, even cracking of the PZT element does not sever the electrodes, or prevent actuation over the full area of the element, or otherwise significantly degrade its performance.

The thin package forms a complete modular unit, in the form of a small "card",
20 complete with electrodes. The package may then conveniently be attached by bonding one face to a structure so that it couples strain between the enclosed strain element and the structure. This may be done for example, by simply attaching the package with an adhesive to establish a thin, high shear strength, coupling through the face with the PZT plates, while adding minimal mass to the system as a whole. The plates may be actuators, which couple
25 energy into the attached structure, or sensors which respond to strain coupled from the attached structure.

In different embodiments, particular electrode patterns are selectively formed on the sheet to either pole the PZT plates in-plane or cross-plane, and multiple layers of PZT
30 elements may be arranged or stacked in a single card to result in bending or shear, and even specialized torsional actuation.

In accordance with a further aspect of the invention, circuit elements are formed in, or with, the modular package to filter, shunt, or process the signal produced by the PZT
35 elements, to sense the mechanical environment, or even to locally perform switching or power amplification for driving the actuation elements. The actuator package may be formed with pre-shaped PZT elements, such as half-cylinders, into modular surface-mount shells suitable for attaching about a pipe, rod or shaft.

Brief Description of the Drawings

These and other desirable properties of the invention will be understood from the detailed description of illustrative embodiments, wherein:

Detailed Description of the Invention

35

Figure 1A illustrates in schema the process and overall arrangement of a prior art surface mounted piezoelectric actuator assembly 10. A structure 20, which may be a structural or machine element, a plate, airfoil or other interactive sheet, or a device or part thereof has a sheet 12 of smart material bonded thereto by some combination of conductive

and structural polymers, 14, 16. An insulator 18, which may be formed entirely or in part of the structural polymer 16, encloses and protects the smart material, while conductive leads or surface electrodes are formed or attached by the conductive polymer. An external control system 30 provides drive signals along lines 32a, 32b to the smart material, and may receive measurement signals from surface-mounted instrumentation such as a strain gauge 35, from which it derives appropriate drive signals. Various forms of control are possible. For example, the strain gauge may be positioned to sense the excitation of a natural resonance, and the control system 30 may simply actuate the PZT element in response to a sensor output, so as to stiffen the structure, and thereby shift its resonant frequency. Alternatively, a vibration sensed by the sensor may be fed back as a processed phase-delayed driving signal to null out an evolving dynamic state, or the actuator may be driven for motion control. In better-understood mechanical systems, the controller may be programmed to recognize empirical conditions, i.e., aerodynamic states or events, and to select special control laws that specify the gain and phase of a driving signal for each actuator 12 to achieve a desired change.

For all such applications, major work is generally required to attach the bare PZT plate to its control circuitry and to the workpiece, and many of the assembly steps are subject to failure or, when quantitative control is desired, may require extensive modeling of the device after it has been assembled, in order to establish control parameters for a useful mode of operation that are appropriate for the specific thicknesses and mechanical stiffnesses achieved in the fabrication process.

FIGURE 1B shows an actuator according to one embodiment of the present invention. As shown, it is a modular pack or card 40 that simply attaches to a structure 20 with a quick setting adhesive, such as a five-minute epoxy 13. While not illustrated, the adhesive attaching the card to the structure or external article 30 may be quite thin, for example, .002-.01 millimeters, and generally is selected to efficiently couple strain between the actuator and the object to which it is attached. In other configurations, the actuator attaches at a point or line. The operations of sensing and control thus benefit from a more readily installable and uniformly modeled actuator structure. In particular, the modular pack 40 has the form of a card, a stiff but bendable plate, with one or more electrical connectors preferably in the form of pads located at its edge (not shown) to plug into a multi-pin socket so that it may connect to a simplified control system 50. As discussed in greater detail below with respect to FIGURE 2C, the modular package 40 may also incorporate planar or low-profile circuit elements, which may include signal processing elements, such as weighting or shunting resistors, impedance matchers, filters and signal conditioning preamplifiers, and may further include switching transistors and other elements to operate under direct digital

control, so that the only external electrical connections necessary are those of a microprocessor or logic controller, and a power supply.

5 In a further embodiment particularly applicable to some low power control situations, a modular package 60 as shown in Figure 1C may include its own power source, such as a battery or power cell, and may include a controller, such as a microprocessor chip or programmable logic array, to operate on-board drivers and shunts, thus effecting a complete set of sensing and control operations without any external circuit connections.

10 The present invention specifically pertains to piezoelectric polymers, and to materials such as sintered metal zirconate, niobate crystal or similar piezoceramic materials that are stiff, yet happen to be quite brittle. It also pertains to electrostrictive materials. As used in the claims below, both piezoelectric and electrostrictive elements, in which the material of the elements has an electromechanical property, will be referred to as electro-
15 active elements. High stiffness is essential for efficiently transferring strain across the surface of the element to an outside structure or workpiece, typically made of metal or a hard structural polymer, and the invention in its actuator aspect does not generally contemplate soft polymer piezoelectric materials. While the terms "stiff" and "soft" are relative, it will be understood that in this context, the stiffness, as applied to an actuator, is approximately that
20 of a metal, cured or highly cross-linked epoxy, high-tech composite, or other stiff material, with a Young's modulus greater than $.1 \times 10^6$, and preferably greater than $.2 \times 10^6$. When constructing sensors, instead of actuators, the invention also contemplates the use of low-stiffness piezoelectric materials, such as polyvinylidene difluoride (PVDF) film and the substitution of lower cure temperature bonding or adhesive materials. In each case, the
25 invention contemplates forming a sheet structure wherein a sheet of piezo material is coupled over a broad surface region to a sheet or film of protective material, and this sheet or film is itself bonded to a surface of, or embedded into an article such that the piezo material acts directly on the article. The principal construction challenges arise with the first class of piezo material noted above, and these will now be described.

30 In general, the invention includes novel forms of actuators and methods of making such actuators, where "actuator" is understood to mean a complete and mechanically useful device which, when powered, couples strain, force, motion or the like to an object or structure. In its broad form, the making of an actuator of the present invention involves
35 "packaging" a raw electro-active element to make it mechanically useful. By way of example, raw electro-active piezoelectric materials or "elements" are commonly available in a variety of semi-processed bulk material forms, including raw piezoelectric material in basic shapes, such as sheets, rings, washers, cylinders and plates, as well as more complex or composite forms, such as stacks, or hybrid forms that include a bulk material with a

mechanical element, such as a lever. These materials or raw elements may, and preferably do, have metal coated on one or more surfaces to act as electrical contacts, or may be non-metallized. In the discussion below, ceramic piezoelectric materials shall be discussed by way of example; although more generally all these forms of raw materials shall be referred to as "elements", "materials", or "electro-active elements". As noted above, the invention further includes structures or devices made by these methods and operating as transducers to sense, rather than actuate, a strain, vibration, position or other physical characteristic, so that where applicable below, the term "actuator" may include sensing transducers.

Embodiments of the invention employ these stiff electrically-actuated materials in thin sheets - discs, annuli, plates and cylinders or shells - that are below several millimeters in thickness, and illustratively about one fifth to one quarter millimeter thick. Advantageously, this thin dimension allows the achievement of high electric field strengths across a distance comparable to the thickness dimension of the plate at a relatively low overall potential difference, so that full scale piezoelectric actuation may be obtained with driving voltages of ten to fifty volts, or less. Such a thin dimension also allows the element to be attached to an object without greatly changing the structural or physical response characteristics of the object. However, in the prior art, such thin elements are fragile, and may break due to irregular stresses when handled, assembled or cured. The impact from falling even a few centimeters may fracture a piezoceramic plate, and only extremely small bending deflections are tolerated before breaking.

In accordance with the present invention, the thin electrically actuated element is encased by layers of insulating material, at least one of which is a tough film which has patterned conductors on one of its surfaces, and is thinner than the element itself, e.g., one-tenth to one-half of the piezo thickness. A package is assembled from the piezo elements, insulating layers, and various spacers or structural fill material, such that altogether the electrodes, piezo element(s), and enclosing films or layers form a sealed card of a thickness not substantially greater than that of the bare actuating element. Where elements are placed in several layers, as will be described below, the package thickness is not appreciably greater than the sum of the thicknesses of the stacked actuating elements.

FIGURE 2A illustrates a basic embodiment 100 of the invention. A thin film 110 of a highly insulating material, such as a polyimide material, is metallized, typically copper clad, on at least one side, and forms a rectangle which is coextensive with or slightly larger than the finished actuator package. A suitable material available for use in fabricating multilayer circuit boards is distributed by the Rogers Corporation of Chandler, Arizona as their Flex-I-Mid 3000 adhesiveless circuit material, and consists of a polyimide film formed on a rolled copper foil. A range of sizes are available commercially, with the metal foils

being of 18 to 70 micrometer thickness, integrally coated with a polyimide film of 13 to 50 micrometer thickness. Other thicknesses may be fabricated. In this commercial material, the foil and polymer film are directly attached to each other without adhesives, so the metal layer may be patterned by conventional masking and etching, and multiple patterned layers may be built up into a multilayer board in a manner described more fully below, without residual adhesive weakening the assembly or causing delamination. The rolled copper foil provides high in-plane tensile strength, while the polyimide film presents a strong, tough and defect-free electrically insulating barrier.

In constructions described below, the film constitutes not only an insulator over the electrodes, but also an outer surface of the device. It is therefore required to have high dielectric strength, high shear strength, water resistance and an ability to bond to other surfaces. High thermal resistance is necessary in view of the temperature cure used in the preferred fabrication process, and is also required for some application environments. In general, polyamide/imides have been found useful, but other materials, such as polyesters with similar properties, may also be used.

In the present constructions, the foil layer of the film is patterned by conventional masking and etch techniques (for example, photoresist masking and patterning, followed by a ferric chloride etch), to form electrodes for contacting the surface of piezo plate elements. Electrodes 111 extend over one or more sub-regions of the interior of the rectangle, and lead to reinforced pads or lands 111a, 111b extending at the edge of the device. The electrodes are arranged in a pattern to contact a piezoelectric element along a broadly-turning path, which crosses the full length and width of the element, and thus assures that the element remains connected despite the occurrence of a few cracks or local breaks in the electrode or the piezo element. Frame members 120 are positioned about the perimeter of sheet 110, and at least one piezoelectric plate element 112 is situated in the central region so that it is contacted by the electrodes 111. The frame members serve as edge binding, so that the thin laminations do not extend to the edge, and they also function as thickness spacers for the hot-press assembly operation described further below, and as position-markers which define the location of piezo plates that are inserted during the initial stages of assembling the laminated package.

FIGURE 2A is a somewhat schematic view, inasmuch as it does not show the layer structure of the device which secures it together, including a further semi-transparent top layer 116 (FIGURE 2B), which in practice extends over the plate 112 and together with the spacers 120 and sheet 110 closes the assembly. A similar layer 114 is placed under the piezo element, with suitable cut-outs to allow the electrodes 111 to contact the element. Layers 114, 116 are preferably formed of a curable epoxy sheet material, which has a cured

thickness equal to the thickness of the metal electrode layer, and which acts as an adhesive layer to join together the material contacting it on each side. When cured, this epoxy constitutes the structural body of the device, and stiffens the assembly, extending entirely over a substantial portion of the surface of the piezo element to strengthen the element and arrest crack growth, thereby enhancing its longevity. Furthermore, applicant has found that epoxy from this layer actually spreads in a microscopically thin but highly discontinuous film, about .0025 mm thick, over the electrodes, bonding them firmly over a substantial region to the piezo plate, but with a sufficient number of voids and pinholes so that direct electrical contact between the electrodes and piezo elements still occurs over a substantial and distributed contact area.

FIGURE 2B shows a cross-sectional view, not drawn to scale, of the embodiment of FIGURE 2A. By way of rough proportions, taking the piezoelectric plate 112 as .2 - .25 millimeters in thickness, the insulating film 110 is much thinner, no more than one-tenth to one-fifth the plate thickness, and the conductive copper electrode layer 111 may have a thickness typically of ten to fifty microns, although the latter range is not a set of strict limits, but represents a useful range of electrode thicknesses that are electrically serviceable, convenient to manufacture and not so thick as to either impair the efficiency of strain transfer from the piezo element through the film, or introduce delamination problems. The structural epoxy 114 fills the spaces between electrodes 111 in each layer, and has approximately the same thickness as those electrodes, so that the entire assembly forms a solid block. The spacers 120 are formed of a relatively compressible material, having a low modulus of elasticity, such as a relatively uncrosslinked polymer, and, when used with a pressure-cured epoxy as described below, are preferably of a thickness roughly equivalent to the piezoceramic plate or stack of elements, so that they form an edge binding about the other components between the top and bottom layers of film 110.

A preferred method of manufacture involves applying pressure to the entire package as the layer 116 cures. The spacers 120 serve to align the piezoceramic plates and any circuit elements, as described below with reference to FIGURES 3-5, and they form a frame that is compressed slightly during assembly in the cure step, at which time it may deform to seal the edges without leaving any stress or irregularities. Compression eliminates voids and provides a dense and crack-free solid medium, while the curing heat effects a high degree of cross-linking, resulting in high strength and stiffness.

An assembly process for the embodiment of FIGURES 2A, 2B is as follows. One or more pieces of copper clad polyimide film, each approximately .025 to .050 millimeters thick in total, are cut to a size slightly larger than the ultimate actuator package dimensions. The copper side of the film is masked and patterned to form the desired shape of

electrodes for contacting a piezo element together with conductive leads and any desired lands or access terminals. A pitchfork electrode pattern is shown, having three tines which are positioned to contact the center and both sides of one face of a piezo element, but in other embodiments an H- or a comb-shape is used. The patterning may be done by masking, etching and then cleaning the clad film, as is familiar from circuit board or semiconductor processing technology. The masking is effected by photoresist patterning, screening, tape masking, or other suitable process. Each of these electroded pieces of polyimide film, like a classical printed circuit board, defines the positions of circuit elements or actuator sheets, and will be referred to below simply as a "flex circuit."

Next, uncured sheet epoxy material having approximately the same thickness or slightly thicker than the electrode foil layer is cut, optionally with through-apertures matching the electrode pattern to allow enhanced electrical contact when assembled, and is placed over each flex circuit, so it adheres to the flex circuit and forms a planarizing layer between and around the electroded portions. The backing is then removed from the epoxy layers attached to the flex circuits, and the pre-cut spacers 120 are placed in position at corners and edges of the flex circuit. The spacers outline a frame which extends above the plane of the electrodes, and defines one or more recesses into which the piezo elements are to be fitted in subsequent assembly steps. The piezo element or elements are then placed in the recesses defined by the spacers, and a second electroded film 111, 112 with its own planarizing/bonding layer 114 is placed over the element in a position to form electrode contacts for the top of the piezo element. If the device is to have several layers of piezo elements, as would be the case for some bending actuator constructions, these assembly steps are repeated for each additional electroded film and piezoelectric plate, bearing in mind that a polyimide film which is clad and patterned on both sides may be used when forming an intermediate electrode layer that is to contact actuator elements both above and below the intermediate sheet.

Once all elements are in place, the completed sandwich assembly of patterned flex circuits, piezo sheets, spacers and curable patterned epoxy layers is placed in a press between heated platens, and is cured at an elevated temperature and pressure to harden the assembly into a stiff, crack-free actuator card. In a representative embodiment, a cure cycle of thirty minutes at 350°F and 50-100 psi pressure is used. The epoxy is selected to have a curing temperature below the depoling temperature of the piezo elements, yet achieve a high degree of stiffness.

The above construction illustrates a simple actuator card having a single piezo plate sandwiched between two electroded films such that the plate transfers shear strain efficiently through a thin film to the surface of the actuator card. The measure of transfer efficiency, given by the shear modulus divided by layer thickness squared, and referred to as

gamma (Γ), depends on the moduli and thickness of the epoxy 114, the rolled foil electrodes 111, and the polyimide film 110. In a representative embodiment in which the epoxy and copper electrode layers are 1.4 mils thick and the epoxy has a modulus of $.5 \times 10^6$, a gamma of approximately 9×10^{10} pounds/inch⁴ is achieved. Using a thinner epoxy layer and film with
5 .8 mil foil, substantially higher Γ is achieved. In general, the gamma of the electrode/epoxy layer is greater than 5×10^{10} pounds/inch⁴, while that of the film is greater than 2×10^{10} pounds/inch⁴.

It should be noted that using PZT actuator plates ten mils thick, a card having
10 two PZT plates stacked over each other with three flex circuit electroded film layers (the middle one being double clad to contact both plates) has a total thickness of 28 mils, only forty percent greater than the plates alone. In terms of mass loading, the weight of the actuator elements represents 90% of the total weight of this assembly. Generally, the plates occupy fifty to seventy percent of the package thickness, and constitute seventy to ninety
15 percent of its mass, in other constructions. Thus, the actuator itself allows near-theoretical performance modeling. This construction offers a high degree of versatility as well, for implementing benders (as just described) as well as stacks or arrays of single sheets.

Another useful performance index of the actuator constructed in accordance
20 with the present invention is the high ratio of actuator strain ϵ to the free piezo element strain Λ , which is approximately (.8) for the two layer embodiment described herein, and in general is greater than (.5). Similarly, the ratio of package to free element curvatures, K, is approximately .85 - .90 for the described constructions, and in general is greater than .7.

Thus, overall, the packaging involved in constructing a piezo element embedded
25 in a flex circuit impairs its weight and electromechanical operating characteristics by well under 50%, and as little as 10%, while profoundly enhancing its hardness and mechanical operating range in other important respects. For example, while the addition of sheet packaging structure to the base element would appear to decrease attainable K, in practical
30 use the flex card construction results in piezo bender constructions wherein much greater total deflection may be achieved, since large plate structures may be fabricated and high curvature may be repeatedly actuated, without crack failure or other mechanical failure modes arising. Several Figures will illustrate the variety of constructions to which such enhanced physical characteristics are brought.

35 First, applicant notes that the structure of an electro-active element embedded between flex circuits not only provides a low mass unified mechanical structure with predictable response characteristics, but also allows the incorporation of circuit elements into or onto the actuator card. FIGURE 2C shows a top view of one device 70 of this type,

wherein regions 71, 73 each contain broad electro-active sheets, while a central region 72 contains circuit or power elements, including a battery 75, a planar power amplification or set of amplifiers 77, a microprocessor 79, and a plurality of strain gauges 78. Other circuit elements 82a, 82b may be located elsewhere along the path of circuit conductors 81 about the periphery. As with the other embodiments, spacers 120 define layout and seal edges of the device, while electrodes 111 attach the electro-active elements to the processing or control circuitry which is now built-in. The planar or other circuit elements 82a, 82b may comprise weighting resistors if the device is operated as a sensor, or shunting resistors to implement passive damping control. Alternatively, they may be filtering, amplifying, impedance matching or storage elements, such as capacitors, amplifiers or the like. In any case, these elements also are located away from electro-active plates 84. The components collectively may sense strain and implement various patterns of actuation in response to sensed conditions, or perform other sensing or control tasks, or may implement a fixed feedback, such as for damping.

15

Returning now to the actuator aspect of the invention, FIGURE 3 shows a top view of an actuator package 200 having dimensions of about 1.25 x 9.00 x .030 inches and assembled with two layers of piezoelectric plates of four plates each. A rectangular polyimide sheet 210 with an end tab 210a carries an electrode 211 in the form of a lattice of H-shaped thin copper lines interconnected to each other and to a single runner 211a that leads out to the tab, thus providing a low impedance connection directly to each of four rectangular regions which hold the piezo plates. The plates themselves are each electroded on both sides with a continuous metal coating.

25

Spacer elements 220a, 220b of H-shape, or 220c of L-shape mark off corners and delineate the rectangular spaces for location of the piezo plates 216. In this embodiment, a plurality of gaps 230, discussed further below, appear between adjacent the H- or L-spacers. As will be apparent from the description below, the use of these small discrete spacer elements (I-, T- or O-shaped spacers may also be convenient) is enhanced because they may be readily placed on the tacky bonding epoxy layer 114 during assembly to mark out assembly positions and form a receiving recess for the piezo elements. However, the spacer structure is not limited to such a collection of discrete elements, but may be a single or couple of frame pieces, formed as a punched-out sheet or molded frame, to provide all, or one or more, orienting and/or sealing edges, or recesses for holding actuation of circuit components.

35

FIGURE 5 illustrates a top view of each of the three sheet, electrode and piezo plate layers separately, while FIGURE 5A illustrates the general layering sequence of the

film, conductor, and spacer/piezo layers. As shown, the spacers 220 and piezo plates 216 constitute a single layer between each pair of electrode layers.

FIGURES 4A and 4B (not drawn to scale) illustrate the layer structure of the assembled actuator along the vertical sections at the positions indicated by "A" and "B" in FIGURE 3. As more clearly shown in FIGURE 4A, a patterned bonding layer of epoxy sheet 214 is coplanar with each electrode layer 211 and fills the space between electrodes, while the spacer 220c is coplanar with the piezo plate 216 and substantially the same thickness as the plate or slightly thicker. Illustratively, the piezo plate 216 is a PZT-5A ceramic plate, available commercially in a five to twenty mil thickness, and has a continuous conductive layer 216a covering each face for contacting the electrodes 211. The spacers 220 are formed of somewhat compressible plastic with a softening temperature of about 250°C. This allows a fair degree of conformability at the cure temperature so the spacer material may fill slight voids 214a (FIGURE 4A) during the assembly process. As shown in FIGURE 4B, the gaps 230 (when provided) between spacers result in openings 214b which vent excess epoxy from the curable bonding layers 214, and fill with epoxy during the cure process. As illustrated in that FIGURE, a certain amount of epoxy also bleeds over into patches of film 215 between the electrodes 211 and the piezo plate 216. Because of the large and continuous extent of electrode 211, this patchy leakage of epoxy does not impair the electrical contact with the piezo elements, and the additional structural connection it provides helps prevent electrode delamination. Thus, the piezo elements are both electrically and mechanically coupled over a broad area to the electroded film.

It will be appreciated that with the illustrated arrangements of electrodes, each vertically stacked pair of piezo plates may be actuated in opposition to each other to induce bending, or more numerous separate electrodes may be provided to allow different pairs of plates to be actuated in different ways. In general, as noted above, the invention contemplates even quite complex systems involving many separate elements actuated in different ways, with sensing, control, and power or damping elements all mounted on the same card. In this regard, great flexibility in adapting the card to practical tasks is further provided by its flexibility. In general, it has a suppl flexibility comparable to that of an epoxy strip thirty mils thick, so that it may be bent, struck or vibrated without damage. It may also be sharply bent or curved in the region of its center line CL (FIGURE 3) where no piezo elements are encased, to conform to an attaching surface or corner. The elements may be poled to change dimension in-plane or cross-plane, and the actuators may therefore be attached to transmit strain to an adjacent surface in a manner effective to perform any of the above-described control actions, or to launch particular waveforms or types of acoustic energy, such as flexural, shear or compressional waves into an adjacent surface.

FIGURE 6 shows another actuator embodiment 300. In this embodiment, illustrated schematically, the epoxy bonding layer, film and spacer elements are not shown, but only electrode and piezo sheets are illustrated to convey the operative mechanisms. A first set of electrodes 340 and second set 342 are both provided in the same layer, each having the shape of a comb with the two combs interdigitated so that an electrical actuation field is set up between the tooth of one comb and an adjacent tooth of the other comb. A parallel pair of combs 340a, 342a is provided on the other side of the piezo sheet, with comb electrode 340 tied to 340a, and comb electrode 342 tied to 342a, so as to set up an electric field with equipotential lines "e" extending through the piezo sheet, and in-plane potential gradient between each pair of teeth from different combs. Here, the piezoceramic plates are preferably not metallized, so direct electrical contact is made between each comb and the plate. If metallized plates are used, they are etched with similar comb patterns in registry with the electrode combs. After electrode attachment, the plates are poled in-plane, by initially applying a high voltage across the two combs to create a field strength above one or two thousand volts per inch between adjacent teeth directed along the in-plane direction. This orients the piezo structure so that subsequent application of a potential difference across the two comb electrodes results in in-plane (shear) actuation.

As shown in FIGURE 7, two such actuators 300 may be crossed to provide torsional actuation when signals are applied to their comb electrodes.

In discussing the embodiments above, the direct transfer of strain energy through the electrode/polyimide layer to any adjoining structure has been identified as a distinct and novel advantage. Such operation may be useful for actuation tasks or diverse as airfoil shape control actuation and noise or vibration cancellation or control. FIGURES 8A and 8B illustrates typical installations of flat (FIGURE 8A) and hemicylindrical (FIGURE 8B) embodiments 60 of the actuator, applied to a flat or slightly curved surface, and a shaft, respectively. When the article to which the actuator is to be attached is built up by molding or laminating, the actuator may be sunk into, embedded within, or laminated into the article, applying its large-area strain coupling into a subsurface region of the article.

However, while the electromechanical materials of these actuators operate by strain energy conversion, applications of the present invention extend beyond strain-coupling through the actuator surface, and include numerous specialized mechanical constructions in which the motion, torque or force applied by the actuator as a whole is utilized. By laminating the elements together with piezo plates, a solid structure is produced in which the plates do not move beyond their elastic or breaking limits, yet retain almost their full actuation efficiency and are able to safely undergo even greater total displacements than in their free state. This results in surprising versatile mechanical devices.

In each of these embodiments, the basic strip- or shell-shaped sealed actuator is employed as a robust, springy mechanical element, pinned or connected at one or more points along its length. As shown in FIGURE 9, when electrically actuated, the strip then functions, alone or with other elements, as a self-moving lever, flap, leaf spring, stack or bellows. In the diagrams of FIGURES 9(a) - 9(q), the elements A, A', A" . . . are strip or sheet actuators such as shown in the above FIGURES, while small triangles indicate fixed or pinned positions which correspond, for example, to rigid mounting points or points of connection to a structure. Arrows indicate a direction of movement or actuation or the contact point for such actuation, while L indicates a lever attached to the actuator and S indicates a stack element or actuator.

The configurations of FIGURES 9(a)-9(c) as stacks, benders, or pinned benders may replace many conventional actuators. For example, a cantilevered beam may carry a stylus to provide highly controlled single-axis displacement to constitute a highly linear, large displacement positioning mechanism of a pen plotter. Especially interesting mechanical properties and actuation characteristics are expected from multi-element configurations 9(d) et seq., which capitalize on the actuators having a sheet extent and being mechanically robust. Thus, as shown in FIGURES 9(d) and (e), a pin-pin bellows configuration may be useful for extended and precise one-axis Z-movement positioning, by simple face-contacting movement, for applications such as camera focusing; or may be useful for implementing a peristalsis-type pump which utilizes the movement of the entire face bearing against a fluid. As noted in connection with FIGURE 3, the flex circuit is highly compliant, so hinged or folded edges may be implemented by simply folding along positions such as the centerline in FIGURE 3, allowing a closed bellows assembly to be made with small number of large, multi-element actuator units. The flex circuit construction allows strips or checkerboards of actuator elements to be laid out with fold lines between each adjacent pair of elements, and the fold lines may be impressed with a thin profile by using a contoured (e.g. waffle-iron) press platen during the cure stage. With such a construction, an entire seamless bellows or other folded actuator may be made from a single flex circuit assembly.

Applicant has further utilized such actuators to perform simple mechanical motions, such as bending, twisting or wiggling, applied to portions of a face mask or puppet for theatrical animation, and has found the actuators to have excellent actuation characteristics and versatile mounting possibilities for small-load, medium displacement actuation tasks of this type.

In general, tasks capable of implementation with pneumatic actuators of small or medium displacement may be addressed using the flex circuit actuator cards of the

invention as discrete mechanical elements, and driven by electrical signals of a few tens of volts. Where the task involves a structure such as a sheet, flap or wall, the flex circuit itself may constitute that structural component. Thus, the invention is suited to such functions as self-moving stirring vanes, bellows or pump walls, mirrors, and the like. In addition, as
5 noted above, tasks involving surface coupling of small displacement acoustic or ultrasonic band frequency are also readily implemented with the low mass highly coupled flex circuit actuators.

As noted above, the piezo element need not be a stiff ceramic element, and if
10 the flex circuit is to be used only as a sensor, then either a ceramic element, or a soft material such as PVDF may be employed. In the case of the piezo polymer, a thinner more pliant low temperature adhesive is used for coupling the element, rather than a hard curable epoxy bonding layer, and more flexible, less stiff or thinner films may be employed.

15 The foregoing description of methods of manufacture and illustrative embodiments is presented to indicate the range of constructions to which the invention applies. The invention having overcome numerous drawbacks in the fragility, circuit configuration and general utility of strain actuators, strain activated assemblies, dampers and sensors, other variations in the physical architecture and practical applications of the modular
20 flex circuit actuators and sensors of the invention will occur to those skilled in the art, and such variations are considered to be within the scope of the invention in which patent rights are asserted, as set forth in the claims appended hereto.

What is claimed is:

CLAIMS

1. An electro-active device comprising a plurality of flex circuits, each having a sheet of film and an electrode on at least one surface of the film, said plurality
5 including at least first and second flex circuits, means forming a recess between said first and second flex circuits, and an electro-active element in said recess having a surface mechanically and electrically coupled to the flex circuits.
2. An electro-active device according to claim 1, constituting a card
10 wherein said element is laminated in the card by a thin layer of curable material.
3. An electro-active device according to claim 2, wherein the curable material is a highly cross-linkable polymer.
4. An electro-active device according to claim 1, wherein the electro-active
15 element is a piezoelectric plate having a thickness under approximately one millimeter.
5. An electro-active device according to claim 4, wherein the piezoelectric plate has a thickness, and first and second cross dimensions, each cross dimension being
20 greater than about ten times the thickness.
6. An electro-active device according to claim 1, wherein the electrodes have an electrode pattern, and said element is bonded to the flex circuit by a planarizing layer of curable sheet material having a pattern complementary to the electrode pattern.
25
7. An electro-active device according to claim 4, wherein the electro-active element has a surface plane, and electrodes of said first and second flex circuits are patterned for applying an electric field which varies in said plane.
8. An electro-active device according to claim 4, wherein the electro-active
30 element has a surface plane, and electrodes of said first and second flex circuits apply an electric field which varies in a direction normal to said plane.
9. An electro-active device according to claim 1, wherein the electrodes
35 have a comb pattern.
10. An electro-active device according to claim 1, comprising two different electro-active elements in two different respective recesses and oriented to produce torsional actuation.

11. An electro-active device according to claim 1, further comprising a circuit element within the device.

5 12. An electro-active device according to claim 11, wherein the circuit element includes at least one of a shunt, a filter, an impedance matcher, a storage element, a power source, an amplifier, and a switch.

10 13. An electro-active device according to claim 11, wherein the circuit element includes a controller.

14. An electro-active device according to claim 1, wherein first and second electro-active elements are connected in different layers of the assembly for moving in different senses.

15 15. An electro-active device according to claim 1, constituting a device selected from among a vane, airfoil, shaker, stepper, stirrer, damper and sonicator.

20 16. An electro-active device according to claim 1, wherein thickness of the device is less than twice a combined thickness of electro-active elements stacked in the device.

17. An electro-active device according to claim 1, wherein the electro-active element is an element selected from among a stack, flexure, shell, plate and bender.

25 18. An electro-active device according to claim 1, configured as one of a pusher, vane, flap, lever, bender, bellows and combination thereof.

30 19. An actuator comprising
a flex circuit having conductors, and
a sheet strain element
wherein the flex circuit is laminated with at least some of its conductors mechanically and electrically coupled to the sheet strain element to form a card having an output face which constitutes a substantially shear-free mechanical coupling to the strain
35 element.

20. An actuator according to claim 19, wherein the flex circuit supports the sheet strain element so that it may be handled freely and is actuated without breakage.

21. An actuator according to claim 19, wherein the sheet strain element has a thickness under several millimeters, and lamination with the flex circuit reduces strain and curvature of said sheet strain element when actuated by less than about thirty percent of free strain and free curvature of said sheet strain element.

22. A method of mechanically perturbing a device, such method comprising the steps of

(i) bonding a card in contact with a region of the device, the card including a sheet of electro-active material laminated to an electroded film, and

(ii) applying an electrical signal to electrodes of the film to create strain energy in the electro-active material, such that strain energy from the electro-active material is coupled through the film across a face of the card into said region and perturbs the device.

23. A method of forming an actuator, such method comprising the steps of forming a flex circuit having conductors arranged in a pattern bonding an electro-active sheet to mechanically couple it to the flex circuit in electrical contact with at least some of said conductors, and assembling the flex circuit and the electro-active sheet with a stiff polymer so as to constitute a card such that the sheet has a non-shear coupling through said flex circuit to an outer face of the card.

24. The method of claim 23, wherein the step of assembling includes assembling circuit elements in said card.

25. A method of forming an electro-active device, such method comprising the step of:

preparing first and second flex circuits with first and second electrodes and a recess formed therebetween, and

bonding at least one electro-active element in the recess in mechanical and electrical contact with said flex circuits over its surface area to form a unitary electro-active structure to apply strain through one of said flex circuits.

26. The method of claim 25, further comprising the step of attaching circuit elements to one of said flex circuits.

27. The method of claim 25, wherein the step of bonding includes bonding plural pairs of electro-active elements together in a laminated card.

28. The method of claim 25, wherein said flex circuits are pliable in a region away from said recess allowing said card to bend in said region and conform to an object.

29. The method of claim 25, wherein the step of preparing includes
5 preparing at least three flex circuits, with electrodes.

30. The method of claim 25, further comprising the step of bonding a surface of one of said flex circuits to an object whereby the device mechanically acts on said object through the flex circuit when signals are applied to the electrode.
10

31. The method of claim 25, wherein the step of bonding said electro-active element is performed with a patterned layer of bonding material co-planar with the electrodes.

32. The method of claim 25, wherein the step of bonding hardens the flex
15 circuits and bonded electro-active element into a card.

33. The method of claim 25, wherein the device constitutes a simple mechanical device selected from among pushers, vanes, flaps, levers, benders, bellows and combinations thereof.
20

34. The method of claim 25, further including the step of providing a resistive shunt to damp excitation of said electroactive element.

35. The method of claim 25 or 34, further including the step of attaching the
25 device to an object to affect mechanical control of the object.
